

A Language Feature to Unbundle Data at Will

—Draft ;; Work in progress—

Anonymous Author(s)

Abstract

Programming languages with sufficiently expressive type theories provide users with different means of data ‘bundling’. Specifically one can choose to encode information in a record either as a parameter or a field, in dependently-typed languages such as Agda, Coq, Lean and Idris. For example, we can speak of graphs *over* a particular vertex set, or speak of arbitrary graphs where the vertex set is a component. These create isomorphic types, but differ with respect to intended use. Traditionally, a library designer would make this choice (between parameters and fields); if a user wants a different variant, they are forced to build conversion utilities as well as duplicate functionality. For a graph data type, if a library only provides a Haskell-like typeclass view of graphs *over* a vertex set, yet a user wishes to work with the category of graphs, they must now package a vertex set as a component in a record along with a graph over that set.

We design and implement a language feature that allows both the library designer and the user to make the choice of information exposure only when necessary, and otherwise leave the distinguishing line between parameters and fields unspecified. Our language feature is currently implemented as a prototype meta-program incorporated into Agda’s Emacs ecosystem, in a way that is unobtrusive to Agda users.

1 Introduction — Selecting the ‘right’ perspective

Library designers want to produce software components that are useful for the perceived needs of a variety of users and usage scenarios. It is therefore natural for designers to aim for a high-level of generality, in the hopes of increased reusability. One such particular “choice” will occupy us here: When creating a record to bundle up certain information that “naturally” belongs together, what parts of that record should be *parameters* and what parts should be *fields*? This is analogous to whether functions are curried and so arguments may be provided partially, or otherwise must be provided all-together in one tuple.

The subtlety of what is a ‘parameter’ — exposed at the type level — and what is a ‘field’ — a component value — has led to awkward formulations and the duplication of existing types for the sole purpose of different uses.

For example, each Haskell typeclass can have only one instance per datatype; since there are several monoids with the datatype `Bool` as carrier, in particular those induced by conjunction and disjunction, the de-facto-standard libraries for Haskell define two isomorphic copies `All` and `Any` of `Bool`, only for the purpose of being able to attach the respective monoid instances to them.

But perhaps Haskell’s type system does not give the programmer sufficient tools to adequately express such ideas. As such, for the rest of this paper we will illustrate our ideas in Agda [?, ?]. For the monoid example, it seems that there are three contenders for the monoid interface:

```
record Monoid0 : Set1 where
  field
    Carrier : Set
    _%_      : Carrier → Carrier → Carrier
    Id       : Carrier
    assoc    : ∀ {x y z} → (x % y) % z ≡ x % (y % z)
    leftId   : ∀ {x} → Id % x ≡ x
    rightId  : ∀ {x} → x % Id ≡ x

record Monoid1 (Carrier : Set) : Set where
  field
    _%_      : Carrier → Carrier → Carrier
    Id       : Carrier
    assoc    : ∀ {x y z} → (x % y) % z ≡ x % (y % z)
    leftId   : ∀ {x} → Id % x ≡ x
    rightId  : ∀ {x} → x % Id ≡ x

record Monoid2
  (Carrier : Set)
  (_%_ : Carrier → Carrier → Carrier)
  : Set where
  field
    Id       : Carrier
    assoc    : ∀ {x y z} → (x % y) % z ≡ x % (y % z)
    leftId   : ∀ {x} → Id % x ≡ x
    rightId  : ∀ {x} → x % Id ≡ x
```

In `Monoid0`, we will call `Carrier` “bundled up”, while we call it “exposed” in `Monoid1` and `Monoid2`. The bundled-up version allows us to speak of a monoid, rather than a monoid on a given type which is captured by `Monoid1`. While `Monoid2` exposes both the carrier and the composition operation, we might in some situation be interested in exposing the identity element instead — e.g., the discrepancy ‘≠’ and indistinguishability ‘≡’ operations on the Booleans have the same identities as conjunction and disjunction, respectively. Moreover, there are other combinations of what is to be exposed and hidden, for applications that we might never think of.

Rather than code with *interface formulations we think people will likely use*, it is far more general to *commit to no particular formulation* and allow the user to select the form most convenient for their use-cases. This desire for reusability motivates a new language feature: The `PackageFormer`.

Moreover, it is often the case that one begins working with a record of useful semantic data, but then, say, for proof automation, may want to use the associated datatype for syntax. For example, the syntax of closed monoid terms is formalised as follows.

```
data Monoid3 : Set where
  _%_ : Monoid3 → Monoid3 → Monoid3
  Id  : Monoid3
```

We can see that this version can also be mechanically obtained from `Monoid0` by discarding ‘non-simple’ fields then turning the remaining fields into constructors.

We show how all these different presentations can be derived from a *single* PackageFormer declaration via a generative meta-program integrated into the most widely used Agda “IDE”, the Emacs mode for Agda. In particular, a package of N constituents with M presentations of bundling results in nearly $N \times M$ lines of code, yet this quadratic count becomes linear $N + M$ by having a single package declaration of N constituents with M subsequent instantiations. It is this massive reduction in duplicated efforts and maintenance that we view as the main contribution of our work.

2 TODO PackageFormers — Being non-committal as much as possible OUTDATED

We claim that the previous monoid-related pieces of Agda code can all be unified as a single declaration which does not distinguish between parameters and fields, where PackageFormer is a keyword with similar syntax as record:

```
PackageFormer MonoidP : Set1 where
  Carrier : Set
  _%_      : Carrier → Carrier → Carrier
  Id       : Carrier
  assoc    : ∀ {x y z} → (x % y) % z ≡ x % (y % z)
  leftId   : ∀ {x} → Id % x ≡ x
  rightId  : ∀ {x} → x % Id ≡ x
```

Coupled with various ‘directives’ that let one declare what should be parameters and what should be fields, we can reproduce the above. Notice that here Carrier has been removed in favour of the name MonoidP, which also is the name of the newly declared entity. This does indeed mean that so far our facility is *single sorted*.

A package former is used via *instantiations*, written as low-precedence juxtapositions of a package former name and an expression of type Variation.

The latter can be built in particular via the following:

```
id       : Variational
record   : Variational
typeclass : Variational
termtyp  : Variational
unbundled : ℕ → Variational
exposing : List Name → Variational
_⊕_      : Variational → Variational → Variational
```

The variationals unbundled and exposing have arguments. While exposing explicitly lists the names that should be turned into parameters, in that sequence, “unbundled n ” exposes the first n names declared in the package former.

An instantiation juxtaposition is written PF v to indicate that the PackageFormer named PF is to be restructured according to scheme v . A *composition* of variationals is denoted using the symbol ‘ \oplus ’; for example, PF $v_1 \oplus v_2 \oplus \dots \oplus v_n$ denotes the forward-composition of iterated instantiations, namely $((\text{PF } v_1) v_2) \dots v_n$, since we take prefix instantiation application to have lower precedence than variational composition. In particular, an empty composition is the identity scheme, which performs no alteration, and has the explicit name *id*. Since PF $\text{id} \approx \text{PF}$ and *id* is the identity of composition, we may write any *instantiation* as a sequence of \oplus -separated clauses: PF $\text{id} \oplus v_1 \oplus v_2 \oplus \dots \oplus v_n$ —which is equivalent to PF $((\text{id} \oplus v_1) \oplus v_2) \dots \oplus v_n$.

0. To make Monoid₀’ the type of *arbitrary monoids* (that is, with arbitrary carrier), we declare:

```
Monoid0' = MonoidP record
```

1. We may obtain the previous formulation of Monoid₁ as follows:

```
Monoid1' = MonoidP record ⊕ exposing (Carrier)
Monoid1'' = MonoidP record ⊕ unbundled 1
```

2. As for Monoid₁, there are also different ways to regain the previous formulation of Monoid₂.

```
Monoid2' = MonoidP record ⊕ unbundled 2
Monoid2'' = MonoidP
              record ⊕ exposing (Carrier; _%_)
```

3. Finally, we mentioned metaprogramming’s need to work with terms:

```
Monoid3' = MonoidP termtyp
```

Of course we may want to have terms *over* a particular variable set, and so declare:

```
Monoid4 = MonoidP termtyp ⊕ renaming (Carrier to Vars) ⊕
```

Since the name Vars does not occur in the MonoidP package former, and is different from the special name Carrier, it is added as a Set parameter together with an injection into the created datatype Monoid₄, which could equivalently be defined as follows:

```
data Monoid4 (Vars : Set) : Set where
  inj : Vars → Monoid4 Vars
  _%_  : Monoid4 Vars
        → Monoid4 Vars → Monoid4 Vars
  Id   : Monoid4 Vars
```

Note that only ‘functional’ symbols have been exposed in these instantiations; no ‘proof-matter’.

For brevity we have only discussed product representations of packages, however the language feature also supports elaborations into nested dependent-sums as in the case where we may have a coherent substructure. Alongside *_unbundled_*, we also have infix combinators for extending an instantiation with additional fields or constructors, and the renaming of constituents according to a user provided String-to-String function. Moreover, just as syntactic datatype declarations may be derived, we also allow support for the derivation of induction principles and structure-preserving homomorphism types. Our envisioned system would be able to derive simple, tedious, uninteresting concepts; leaving difficult, interesting, ones for humans to solve.

The PackageFormer language feature unifies disparate representations of the same concept under a single banner. How does one actually *do* anything with these entities? Are we forced to code along particular instantiations? No; unless we desire to do so.

3 TODO Variation Polymorphism OUTDATED

Suppose we want to produce the function *concat*, which composes the elements of a list according to a compositionality scheme — examples of this include summing over a list, multiplication over a list, checking all items in a list are true, or at least one item in the list is true. Depending on the selected instantiation, the resulting function may have types such as the following:

```

1  concat0 : {M : Monoid0}
2           → let C = Monoid0.Carrier M
3             in List C → C
4
5  concat1 : {C : Set} {M : Monoid1 C} → List C → C
6
7  concat2 : {C : Set} {_%_ : C → C → C}
8           {M : Monoid2 C _%_} → List C → C
9
10 concat3 : List Monoid3 → Monoid3

```

An attempt to unify these declarations requires understanding exactly *which type is referred to by the phrase MonoidP*. For the termtype variation, it can only refer to the resulting algebraic data-type; whereas for the record variation, it could refer to the result record type *or* to the Carrier projection of such record types. Consequently, we use monad-like notation $\text{do } \tau \leftarrow \text{MonoidP}; \dots \tau \dots$ whenever we wish to refer to *values* of the underlying carrier of a particular instantiation, rather than referring to the type *of* such values. For example:

```

21  do  $\tau \leftarrow \text{MonoidP record}; \mathcal{B} \tau$ 
22   $\approx \lambda \{\tau : \text{MonoidP record}\} \rightarrow \mathcal{B} (\text{MonoidP.Carrier } \tau)$ 
23
24  do  $\tau \leftarrow \text{MonoidP termtype}; \mathcal{B} \tau$ 
25   $\approx \mathcal{B} (\text{MonoidP termtype})$ 
26

```

This lets us write the following *variation polymorphic* programs:

```

27  concatP : {v : Variation}
28           → do  $\tau \leftarrow \text{MonoidP } v; \text{List } \tau \rightarrow \tau$ 
29
30  concatP [] = MonoidP.Id
31  concatP (x :: xs) = x % concatP xs
32  where _%_ = MonoidP._%_
33

```

It is important at this juncture to observe that the type of `concatP` depends crucially on the variation `v` that is supplied, or inferred. This is a prime reason for using a dependently-typed language as the setting for the `PackageFormer` feature.

4 TODO Next Steps

OUTDATED

We have outlined a new unifying language feature that is intended to massively reduce duplicated efforts involving different perspectives of datatypes. Moreover, to make this tractable we have also provided a novel form of polymorphism and demonstrated it with minimal examples.

We have implemented this as an “editor tactic” meta-program. In actual use, an Agda programmer declares what they want using the combinators above (inside special Agda code comments), and these are then elaborated into Agda code.

We have presented our work indirectly by using examples, which we hope are sufficiently clear to indicate our intent. We next intend to provide explicit (elaboration) semantics for `PackageFormer` within a minimal type theory.

Moreover there are a number of auxiliary goals, including:

1. How do users extend the built-in `Variations` type along with the intended elaboration scheme.

One possible route is for a user to ‘install’ a new variation by specifying where the separation line between parameters and fields happens; e.g., by providing a function such as `List Constituent → Pair (List Constituent)`,

which may introduce new names, such as the aforementioned `Carrier` and `Vars`.

2. Explain how generative modules [?] are supported by this scheme.
3. Demonstrate how boilerplate code for renamings, hidings, extensions, and the flattening of hierarchical structures can be formed; [?].
4. How do multiple default, or optional, clauses for a constituent fit into this language feature.
5. Flexible polymorphic definitions: One should be able to construct a program according to the most convenient presentation, but be able to have it *automatically* applicable to other instantiations; [?].

For example, the `concat` function was purely syntactic and the easiest formulation uses the algebraic data-type rendition, whence one would write `concat : List MonoidP termtype → MonoidP termtype` and the variation is found, then systematically generalised to obtain

```

concatP : {v : Variation}
          → do  $\tau \leftarrow \text{MonoidP } v; \text{List } \tau \rightarrow \tau$ 

```

When there are multiple variations mentioned, the problem becomes less clear cut and the simplest solution may be to simply indicate which variation or occurrences thereof is intended to be generalised.

Finally, the careful reader will have noticed that our abstract mentions graphs, yet there was no further discussion on that example. Indeed, one of the next goals is to accommodate multi-sorted structures where sorts may *depend* on one another, as edge-sets depend on the vertex-set chosen.

There are many routes to progress on this fruitful endeavour.

We have a complete prototype available on github, which we will link to once the paper is no longer double-blind.
